Information Contents of Inflation Indexed Bond Prices: Evaluation of U.S. Treasury Inflation-Protection Securities

Yukinobu Kitamura*

Abstract

In January 1997, the U.S. Treasury started issuing Treasury Inflation-Protection Securities (TIPS; hereafter TIPS and indexed bonds interchangeably) and, as of September 2002, a total of ten issues were being traded on the market, while one issue had already matured. The purpose of this paper is to attempt an evaluation of indexed bonds based on the record of five and a half years of market trading in TIPS, and to present the results as a reference for the issue of similar securities by the Japanese government in the future. The results of this paper are as follows: (1) Real interest rates are relatively stable and remain near the 4% mark. The 30 year bond is even more stable. (2) The expected inflation rate is more closely linked to realized CPI than to the real yield. However, the expected inflation rate is far more stable and its fluctuations smaller. In particular, the 30 year bond is steady, near the 2% mark. (3) While the economic information derived from the 10 year bond is strongly influenced by short-term economic fluctuations, the economic information derived from the 30 year bond is generally unresponsive to short-term economic fluctuations. (4) Examination of the derived information using econometric methods indicates that useful economic information was obtained from the following indexed bonds in the secondary markets: Series Three and Four 10 year bonds. Information included in the expected inflation rate was useful for the Series Three and Four 10 year bonds. Hence, while a total of eleven indexed bonds have been issued, very few of them have proven to be truly useful. These useful bonds turn out to have fair initial conditions, continuous arbitrages with the nominal bonds, and active trades in the secondary markets.

Key words: Inflation Indexed Bond; Expected Inflation Rate; Real Yield.

JEL classification: E31, E44, G14

* Professor, Hitotsubashi University (E-mail: kitamura@ier.hit-u.ac.jp)

I am indebted to Mr. Toyoichiro Shirota of the Institute for Monetary and Economic Studies of the Bank of Japan for the collection of data used in this paper. I am also indebted to Ms. Yuko Fujiki for developing a Matlab program for the computation of real yields and expected inflation rates, and to Ms. Michiko Baba for creating the tables and figures. This paper was presented at Annual Meeting of Japan Economic Association in 2003, Meiji University, I am grateful for Professor Naoyuki Yoshio for his valuable comments. This study was supported in part by funds made available by the Japanese Bankers Association Fund for the Promotion of Academic Research. I take this opportunity to express my gratitude.

Table of Contents

1. Introduction

In January 1997, the U.S. Treasury started issuing Treasury Inflation-Protection Securities (TIPS; hereafter TIPS and indexed bonds interchangeably.) and, as of September 2002, a total of ten issues were being traded on the market, while one issue had already matured. The purpose of this paper is to attempt an evaluation of indexed bonds based on the record of five and a half years of market trading in TIPS, and to present the results as reference for the issue of similar securities by the Japanese government in the future.

Table 1 provides the simplest form of comparison for the five year indexed bond that matured in July 2002 by pairing it with the nominal bond with the closest issue (maturity) date. The indexed bond paid back a total of $131.5344, while the paired nominal bond paid $130, indicating that the government did not recoup the cost of the finances involved. On the other hand, investors did not substantially benefit during this period from the opportunity of being able to avoid inflationary risks by holding the indexed bond. Hence, the yield was not particularly high. An objective assessment of the figures indicates that the market mechanism had worked towards achievement of ex-post arbitrage. A more detailed review of the cash flow of the indexed bond shows that interest payment amounted to $19.2681, while the inflation-adjusted principal amounted to $112.2664. As the nominal bond generated $30 in interest payments, the nominal bond outperformed the indexed bond in the area of interest cash flow. However, the redeemed principal of the indexed bond was substantially larger, as the principal was indexed.[1]

Indexed bonds have been issued by a total of 30 countries. Major examples of such issues are outlined in Table 2, which shows that in most instances the issuance of indexed bonds began after the start of the 1990s. While this in part reflects the actions taken by such high-inflation countries as Brazil, Turkey and Mexico, several factors have contributed to growing demand for long-term financial products with built-in inflation hedges. Since their first introduction in the United Kingdom in 1981, pension funds, life insurance companies and other institutional investors have been increasingly drawn to indexed bonds, in light of the aging of society. Indexed bonds also provide various advantages to issuers and have come to be recognized as a standard financial asset issued by governments. For instance, they have been used as a means for inflation control and fiscal discipline to bolster market confidence. Furthermore, the expected inflation rate can be

[1] In the U.K., the coupons are stripped and traded separately. Indexed bonds are back-loaded in the sense that cash flow increases in the second half as maturity nears because of the inflation adjustment effect.

unambiguously derived from market prices. With the adoption of inflation targeting by a growing number of countries during the 1990s, most of them issue indexed bonds to serve as a source of market information on inflation.[2]

This paper is organized as follows. Section 2 describes how U.S. Treasury Inflation-Protection Securities are traded. Section 3 compares the indexed bonds with the nominal bonds in terms of coupon rates and market prices, and examines the statistical properties of the real yields and expected inflation rates. In section 4, the purpose here is not to define a specific price model for indexed bonds, but rather to identify the features of price formation. In concrete, we verify the efficiency of the bond market by testing for the random walk hypothesis and examine whether bond prices are being affected by other market information. As such, we are interested in determining whether fluctuations in trading prices are being significantly affected by factors other than changes in the expected rate of inflation, such as the prices of other financial products, equities, foreign exchange rates, the Federal Fund (FF) rate and bid-ask spreads. In Section 5, expected inflation rates derived jointly from the indexed and nominal bonds are examined econometrically. Information contents of expected inflation rates are evaluated by the inflation forecasting model and the federal fund rate forecasting model. Section 6 provides a summary in the form of an evaluation of the U.S. Treasury Inflation-Protection Securities for the first five and a half years.

2. Structure of U.S. Treasury Inflation-Protection Securities

As of June 2001, the outstanding balance of U.S. Treasury Inflation-Protection Securities (TIPS) amounted to $129.3 billion, equivalent to 2.3% of the total outstanding U.S. government bonds. Compared to the United Kingdom, where indexed bonds held a 24.0% share as of September 2001, the U.S. figures indicate that market scale remains small.

The structure of TIPS can be summarized as follows.

[2] Countries appearing in Table 2 which have adopted inflation targeting are Australia, Brazil, Canada, Chile, Czech Republic, Israel, New Zealand, Poland, Sweden and The United Kingdom. In order to control inflation via day-to-day monetary operations, the central banks need daily information about the expected inflation rates, rather than one month lagged CPI monthly data. For this sake, it is desirable to obtain daily expected inflation rates by issuing inflation indexed bonds. Note, however, that many countries having issued indexed bonds have not adopted inflation targeting and that information from indexed bonds can be useful for other monetary policy objectives.

Firstly, ensuring the real value of interest and principal requires indexation. The Treasury Department does this by multiplying the principal by the ratio between CPI-U (Consumer Price Index for All Urban Consumers) as measured three-months prior to settlement date and CPI-U for the first issue date. Specifically, the following formula is used.

$$(1) \qquad IR_{SD} = \frac{RefCPI_{SD}}{RefCPI_{FID}}$$

Daily CPI values are linearly interpolated using CPI for the first of the month and the first of the following month.

$$(2) \qquad RefCPI_{SD} = \frac{RefCPI_{M+(t-1)}}{D \cdot (RefCPI_{M+1} - RefCPI_{M})}$$

Where D = number of days in month, t = settlement date, Ref CPI_M= CPI for first day of month M, Ref CPI_{M+1}= CPI for first day of M+1 month.

Inflation compensation (IC) is defined as the difference between the indexed and nominal principals.

$$(3) \qquad IC_{SD} = (Prin \cdot IR_{SD}) - Prin$$

Twice-a-year interest payments are computed as follows.

$$(4) \qquad IP_{DD} = \frac{c}{2}(Prin + IC_{DD})$$

Where c = annual coupon rate, PD=interest payment date.

Given this definition, the relation between the price and interest payments of TIPS in the secondary market can be expressed as follows.[3]

[3] The U.S. Treasury Department guarantees that principal at redemption will not fall below the nominal value, 100 even under deflation. This points to an asymmetry in indexation in the sense that U.S. Treasury Inflation-Protection Securities are adjusted to guarantee real values under inflation, while nominal values are guaranteed under deflation. As opposed to this, U.K. indexed bonds are also adjusted under deflation to guarantee real amounts. The fact that U.S. indexed bonds guarantee the nominal value of the principal implies that a call option comes into play under deflation. Strictly speaking, the price of this option should also be calculated. This paper does not consider tax either.

(5) (Nominal) Price per $100 face value
= Inflation-Adjusted Price + Inflation-Adjusted Accrued Interest

This relation can be specified as follows.

$$(6)\qquad P_{ib} = \frac{Ref\mathrm{CPI}_{\mathrm{setdate}}}{Ref\mathrm{CPI}_{\mathrm{first}}}\left[\left(\frac{1}{1+\frac{f}{d}\cdot\frac{r}{2}}\right)\times\left\{\frac{C_{ib}}{2}+\frac{C_{ib}}{2}\sum_{h=1}^{n}\left(\frac{1}{1+\frac{r}{2}}\right)^{h}+100\left(\frac{1}{1+\frac{r}{2}}\right)^{n}\right\}-\frac{C_{ib}}{2}\left(\frac{d-f}{d}\right)\right]$$

Where, P_{ib} = the market price of indexed bond,
d = number of days between interest payment dates,
f = number of days between settlement date and next interest payment date,
n = number of interest payments between next interest payment date and maturity,
C_{ib} = real coupon rate of TIPS,
r = real yield. During the last six months to maturity, cash flow is discounted based on simple interest instead of compound interest.

Similarly, the price of nominal bonds can be expressed as follows.

$$(7)\qquad P_{nb} = \left(\frac{1}{1+\frac{g}{e}\cdot\frac{R}{2}}\right)\left[\frac{C_{nb}}{2}+\frac{C_{nb}}{2}\sum_{j=1}^{m}\left(\frac{1}{1+\frac{R}{2}}\right)^{j}+100\left(\frac{1}{1+\frac{R}{2}}\right)^{m}\right]-\frac{C_{nb}}{2}\left(\frac{e-g}{e}\right)$$

Where, P_{nb} = the market price of nominal bond,
e = number of days between interest payment dates,
g = number of days between settlement date and next interest payment date,
m = number of interest payments between next interest payment date and maturity,
C_{nb} = Nominal coupon rate,
R = nominal yield.

The following relation holds when arbitrage takes place between the nominal bond and TIPS interest rates.

Because (1+r) x (1+π) = (1 +R)

(8) $$r = \frac{1+R}{1+\pi} - 1 = \frac{R-\pi}{1+\pi} \quad \text{or} \quad \pi = \frac{R-r}{1+r}$$

In other words, if the yield of the nominal bond (R) and the yield of TIPS (r) are known, it is possible to compute the expected inflation rate (π).

3. Overview of TIPS

3.1 Conditions at issuance and price spreads

Let us review the data used in this paper. Table 3 provides a summary of conditions at issuance and market price spreads between the indexed and nominal bonds.
The prices of nominal bonds are constantly higher for the Series One 10 years and Series Three 30 years and its standard deviations of prices are higher accordingly. Those for the Series One and Two 30 years are constantly higher for the indexed bonds. The price spreads in the 30 years bonds may exist due to the inflation risk premium for the long term securities, given the coupon rate spreads are, more or less, the same as for the 10 year bonds.
The price spreads for the Series One 5 years, the Series Two-Seven 10 years are not so large, the time series of market prices reveal equilibrium between the indexed and nominal bonds.
Among these indexed bonds, the Series One 5 year bond has already reached its maturity and been redeemed. This bond is ignored below. The Series Seven 10 year bond has issued just recently and therefore sufficient information is not available at present, so is omitted from this paper.

3.2 Real Yields

Let us review the characteristics of real yields obtained from eq (6) (see Fig 1). Real yields continued to climb between February 1997 and February 2002, and thereafter declined. However, the real yield of almost all indexed bonds remains in the 3% range. In this context, real yields are higher for bonds with earlier issue dates and lower for more recent issues. For instance, there is a differential of roughly 2% between the Series One 10-year issue of February 6, 1997 and the Series Six 10-year issue of January 15, 2002.

A careful examination of Table 4 and Figure 1 shows that real yield computed using our method traces a clean term structure. However, indexed bonds only have a history of five and a half years, while most issues have maturates of 10 or 30 years. Hence, the market is divided into two segments: bonds with five to ten years remaining to maturity, and bonds with 26 to 30 years remaining. The intermediate period of 10 to 25 years is currently empty. Assuming that the Treasury Department will continue to issue indexed bonds every year, it will still take 15 years to achieve a remaining-period structure with no gaps between zero and 30 years. Figure 2 provides a conceptual diagram of the real interest term-structure based on yields computed at the present time.

Table 5 shows correlations for the real yield that we have calculated. Correlations are high among 10 year bonds and among 30 year bonds, while the correlation between 10 year and 30 year bonds is quite low. The levels of Figure 1 and Table 4 also confirm that our computed real yield has remained steady at high levels in recent years. Sack and Elsasser (2002) have stated that, given the real yield that they have computed, the recent growth in demand for indexed bonds is puzzling.[4] However, based on our data, there is no puzzle here.

Kitamura (1997) computed the real yields for inflation-indexed U.K. government bonds to also find extremely stable trends.[5] This may be explained as follows. If we assume that real yields to a certain degree reflect productivity in the real economy, there is no reason to expect sharp fluctuations.[6] It can be inferred that U.S. real yields, which have been generally stable in the 4% range, reflect the trend in real productivity of the U.S. economy. While real yields may fluctuate in response to economic conditions, the level of fluctuation is far smaller than that of the nominal yields observed in the financial markets.

---

[4] According to Sack and Elsasser (2002, pp.5-7), they seem to use the simplified method of derivation of real yield and expected inflation rate as used by the Bloomberg discussed in Appendix. Their data series differ from ours.

[5] The U.K. inflation indexed bonds were issued 16 years earlier than the U.S. ones. Its structure was much more complicated. See Kitamura (1995) for the formal structure of the U.K. indexed bonds and derivations of real yields and expected inflation rates. Kitamura (1995) obtained the real yields and expected inflation rates by using monthly data (the end of the month data) and combining different series of bonds.

[6] The real yields from the indexed bonds are determined in the financial market, given the expected inflation rates of the investors. Its movements differ substantially from those of the ex-post real yields obtained from the nominal yields minus the realized historical inflation rate. In general, the expected inflation rate is more stable than the realized historical inflation rate.

3.3 Expected Inflation Rates

Assume that pairs of nominal and indexed bonds continue to satisfy arbitrage conditions. Using the procedures outlined in Section 2 to obtain the nominal yield of nominal bonds and the real yield of indexed bonds, the expected inflation rate can then be defined as the differential between the two yields.[7] The information produced using this method forms the basis of this paper. In a stricter sense, to say that arbitrage is being conducted between nominal and indexed bonds implies that market prices are in equilibrium. Expected inflation rates can be used only in the cases that the pairs are genuinely in equilibrium. This is a subset of all information derived above and the data become discontinuous. We were able to utilize all of the paired information by relaxing arbitrage conditions.
Figures 3 and Tables 6-7 depict our computer projections for rates of inflation and realized CPI. Regarding the expected inflation rate, unlike the real yields cited above, the computed expected inflation rate fluctuates more widely, and is highly correlated to CPI. Particularly after the start of 2001, the expected inflation rate derived from 10-year bonds has traced a downward trend closely paralleling that of the CPI. In the case of 30-year bonds, no short-term correlation with CPI trends is formed.

4. Econometric Analysis of the Market Price of Indexed Bonds

4.1 Unit-Root Test

First, in order to identify the statistical properties of the market price of indexed bonds, we use the Dicky-Fuller Test and the Phillips-Perron Test[8] to test whether individual indexed bond prices follow a random walk.

The results are summarized in Table 8. In all cases, the null hypothesis that a unit-root exists cannot be rejected at the 1% significance level. That is, based on the data used, the hypothesis that indexed bond prices follow a random walk cannot be rejected.

[7] This formula includes risk premium and liquidity premium that are the subjective variables over time. It is important to identify empirically these premiums from expected inflation rates. In fact, from our experiences, we can consider both risk and liquidity premiums have been negligible or near constant if not negligible, at least for the 10 years bonds over the sample period.

4.2 Estimating the Price of Indexed Bonds Using Additional Financial Market Information

While the unit-root test showed that the proposition that indexed bond prices follow a random walk cannot be rejected, this does not imply that other economic information has no impact on prices. To examine this possibility, we undertook a regression analysis of indexed bond prices and the (indexed) prices of other financial assets, interest rates, foreign exchange rates, and bond prices themselves against lags of 1, 7, 15 and 30 days. The results are summarized in Table 9.

The results indicate excellent fit when the entire series of estimation equations are evaluated based on the values of adjusted R-squares. However, diagnostic tests show that the specification of several models generates problems in the light of other statistical properties. For instance, the RESET test indicates that there were no problems in specifying the models for the Series Four 10 year, Series Two 30 year, Series Five 10 year, and Series Six 10 year and that in all other instances, the models seem to be incorrectly specified.[9] The heteroskedasticity test is designed to verify whether the distribution of the error terms of additional independent variables is subject to variance.[10] This test revealed that heteroskedasticity problems existed for all indexed bonds. This points to the possibility that prices were caused to fluctuate due to certain shocks or new information during the estimation period that could not be controlled by the independent variables. Regarding autocorrelation, the standard Durbin-Watson statistic cannot be used because lag terms of the dependent variable are included in the independent variables. Instead, Durbin's alternative statistic was used. The results showed autocorrelation in all estimations with the exception of the Series Two 10 year and Series Six 10 year bonds. This suggests two possibilities: the inclusion of endogenously determined independent variables, or incorrect specification of the model.

An examination of the estimation equation itself indicates that prices of all nominal bonds paired with the indexed bonds have a significantly positive effect. The coefficient of the FF rate is always positive, but not significant. The Dow-Jones Industrial index has a significant positive effect in all cases other than the Series Six 10 year issue. On the other

---

[8] For detail in diagnostic tests, see Hamilton (1994, P.514). Campbell, Lo and MacKinlay (1997, Chap 2) suggests various tests for autocorrelations and variance ratios, in addition to unit root test for random walk in financial statistical data.

[9] Proposed by Ramsey (1969) and generally known as the RESET test. The RESET test examines whether some independent variables have been omitted in the specification of the model. This is done by adding the second, third and fourth terms of the dependent variable to the independent variables and verifying the significance of their coefficients.

[10] See Cook and Weisberg (1983).

hand, the S&P 500 index has a significant negative effect.[11] This may simply mean that we must make a choice between the better of the two stock indices. During the first half of the sample period, the New York Stock Exchange was very active, and the NASDAQ price index also had a significantly positive effect. However, during the second half, with the exception of the Series Five 10 year issue, the level of significance of the coefficients declined, or their signs changed to negative.

The yen-dollar rate and the mark-dollar rate were not very significant and their coefficients underwent sign changes. Among AR(1), AR(7) and AR(30) of the indexed bond price, only AR(1) was significant. Although the coefficient was not 1, it was fairly close to 1. While this is related to the unit-root test summarized in Table 8, the finding implies that autocorrelation is the main factor affecting fluctuations in price. A more detailed look reveals that this tendency was particularly strong in the cases of the Series One 10 year, Series Three 10 year, Series Five 10 year, Series One 30 year and the Series Two 30 year issues. How should this be interpreted?

Why would price differentials persist between indexed bonds and nominal bonds issued and maturing at essentially the same time? The following general reasons can be posited. (1) Preference for one type of bond during the auction process creates price distortions which persist in the secondary markets. (2) Professional bond dealers are very active participants in the secondary market for nominal bonds, which is used for various hedging purposes. On the other hand, participants in the secondary market for indexed bonds are limited, and the market is not widely used for hedging purposes. This situation could change if the private sector started issuing inflation-indexed corporate bonds and if inflation-indexing were to be built into economic contracts. While this would certainly spur demand, the secondary market as it stands now does not have adequate depth.

Thus, the pairing information leads us to make the following inference. In the case of indexed bonds for which lagged variables have high explanatory power, transaction volumes may be low because arbitrage does not occur in the secondary markets. As this can be checked using the bid-ask spread for indexed bonds in the secondary markets, the bid-ask spread has been included in the independent variables.[12] The coefficient is significant for the Series Three 10 year and Series Four 10 year. For these issues, it is shown that a widening in the bid-ask spread is associated with a rise in the price of the

[11] The coefficient for Series Six 10-year bonds is positive but not statistically significant.
[12] Fleming [2003] argues that the bid-ask spread is a useful indicator of market liquidity of the U.S. Treasury Securities.

indexed bond (positive coefficient). This can be explained as follows. A widening in the bid-ask spread implies reduced liquidity, which in turn raises the liquidity risk premium and results in a higher price for the bond. If we assume that the bid-ask spread exerts almost no impact on the bond price when trading demand is weak because the secondary market is extremely quiet, we are led to conclude that the secondary market is functioning to some degree in the case of the above-mentioned Series Three 10 year and Series Four 10 year.

5. Econometric Analysis of Expected Inflation Rates

In this section, we examine, by means of econometric techniques, whether the real yields and expected inflation rates derived from the market prices can provide useful information for monetary policy. In particular, we compare nine series of expected inflation rates, identify the best information and supply reasonstherefore. This has certain ramifications for policy-making.

There are at least three empirical models concerning expected inflation rates. First is the inflation forecasting model in which the officially announced CPI is explained by its own lags and expected inflation rates from the indexed bonds. Second is the inflation expectation formation model in which the expected inflation rate is explained by its own lags and other relevant variables. Third is the Federal Fund Rate forecasting model that is explained by the lagged expected inflation rates. This model actually evaluates whether the expected inflation rates can provide useful information for monetary policy, i.e. the Federal Fund Rate formation.

As the officially announced CPI is monthly data, the daily CPI inflation rates are calculated by a year-on-year change from the linear extrapolation of the monthly CPI. According to Figure 3, the daily changes of extrapolated CPI are very little, if any, compared with the expected inflation rates from the indexed bonds. It may thus not be appropriate to build the official CPI inflation forecasting model based on the expected inflation rate.[13] We will focus on the other two models below.

[13] In fact, we estimated the CPI inflation forecasting model that is explained by its own lags, expected inflation rates and other relevant variables. Apart from the significance of the first lag of CPI inflation, explanatory powers of other variables, particularly the expected inflation rate, vary among different series of indexed bonds. Overall explanatory power of them seems very limited.

5.1 Unit Roots Test

Table 10 reports the results of the unit roots test of expected inflation rates. Except for Series One and Two 30 year indexed bonds, the existence of unit roots cannot be rejected. This implies that the expected inflation rate one day prior explains almost all variations of the day and that the time series of expected inflation rates is non-stationary, in a statistical sense.

5.2 Inflation Expectation Formation

The purpose of the CPI forecasting model is to examine how accurately the official CPI can be traced, not to identify how inflation expectations are formulated. This sectionis concerned with the mechanism of inflation expectation , utilizing the expected inflation rate obtained from the indexed bonds.

Table 10 displays the results of the unit root test for expected rates of inflation derived from the Series Three 10 year bond and the Series Four 10 year bond. Null hypothesis of existence of unit root cannot be rejected at the 1% significance level. This means that the link between the previous day's expected inflation rate and today's expected inflation rateis quite strong.

Table 11 further examines whether the inflation expectation formation model can be improved through the addition of financial market variables. The model is based largely on the previous day's expected rate, but is also influence by other financial variables and expected rates that existed two or more days prior thereto.

Although coefficient of determinant (R square) is significantly high as 0.99, diagnostic statistics indicate signs of serial correlation and heteroskedasticity, the model may omit some variables or/and may be misspecified.

The public announcement of the CPI usually takes place in the middle of the month,[14] which provides information up to the end of the last month (an approx. 15 day lag). This information lag increases gradually thereafter and reaches a 45 day lag at maximum. That is to say, since the information lag varies from 15 days to 45 days, the CPI

[14] Although the date of public announcement of CPI varies from month to month, it is usually in between 15th and 20th of the month. Announcement time is 8:30 am in the eastern daylight time, that is before the financial markets open. This information is taken in to account of the announcement day's trading.

announcement amounts to information equivalent to about 30 days. Table 11 examines the effect of the announcement day (using a dummy variable for announcement date = 1, otherwise = 0) on the expectation formation (see Figure 4). During the sample period, the announcement of CPI reduces the expected inflation rate by 0.01%. This effect is not statistically significant, and other market information released between the CPI announcement dates has a greater bearing on the regularity of inflation expectation formation.

5.3 Federal Fund Rate Forecasting Model

The forecasting model of the Federal Fund Rate, the main policy instrument of The Federal Reserve Board of The United States, is reported in Table 12. The model contains 15 lagged Federal Fund Rates, the lagged expected inflation rates, and the dummy variable for the CPI announcement date. In so doing, the same Federal Fund Rate can be explained by different expected inflation rates from different series of indexed bonds, and thus its information contents can be compared over different indexed bonds. Note, however, that we cannot compare the forecasting performance for exactly the same duration because of different issue dates and maturates.

Judging from the goodness of fit, i.e. coefficient of determination (R square), Series Three, Four and Five 10 years and Series Two 30 years exceed 0.99. Significance test for coefficients of the expected inflation rates implies whether the expected inflation rates have a significant influence on the Federal Fund Rates.[15] Series Two, Three and Four 10 years were significant.

Combining the statistical results, informational contents of Series Three and Four 10 year bonds seem to surpass those from other bonds. Based on this assumption, the attractive bond prices shown in Tables 3 and 9 appear to have triggered active secondary market trades.

6. Evaluation of Indexed Bonds

The preceding analysis indicates that our derived real interest rates and expected rates of inflation have the following characteristics.

[15] This is basically equivalent to the Granger causality test.

(1) Real interest rates are relatively stable and remain near the 4% mark. The 30 year bond is even more stable.

(2) The expected inflation rate is more closely linked to realized CPI than to the real yield. However, the expected inflation rate is far more stable and its fluctuations smaller. In particular, the 30 year bond is steady, near the 2% mark.

(3) While the economic information derived from the 10 year bond is strongly influenced by short-term economic fluctuations, the economic information derived from the 30 year bond is generally unresponsive to short-term economic fluctuations.

(4) Examination of the derived information using econometric methods indicates that useful economic information was obtained from the following indexed bonds in the secondary markets: Series Three and Four 10 year bonds. Information included in the expected inflation rate was useful in the cases of the Series Three and Four 10 year bonds. Hence, while a total of eleven indexed bonds have been issued, very few of them have proven to be truly useful. The conclusion of this paper is that the Series Three and Four 10 year bonds are the only ones that can be really used. These bonds turn out to have fair initial conditions, continuous arbitrages with the nominal bonds, and active trades in the secondary markets.

(5) On the other hand, informational contents of expected inflation rates from the indexed bonds are limited, provided that the issue conditions are not fair, that a wide gap in issuing dates between the paired index and nominal bonds exists, that issue conditions for the nominal bonds are not inadequate, and that trades in the secondary markets are absent. Series One[16] and Five[17] 10 year bonds and Series Three[18] 30 year bond are cases in point.

Some issues and problems remaining for future discussion can be summarized as follows.

(1) In the spring of 2002, The U.S. Treasury Department announced it would continue to actively and regularly issue the indexed bonds (TIPS). It still needs a long time to

[16] The market demand for the first indexed bond overwhelm its supply so that the price is too high (i.e. the coupon rate is too low), thus no arbitrage with the nominal bond is taken place.
[17] In this case, the problem does not lie in its pricing but in its issue amount differences, i.e., the nominal bonds were issued more than twice as much as the indexed bonds.
[18] In this case, there are substantial differences in coupon rates and issue amounts between the indexed and nominal bonds, although it may be too early to conclude anything definitive.

accumulate sufficient information to construct the complete term structure of the indexed bonds. Comparisons of the term structure of interest rates between the nominal and indexed bonds and constructions of the term structure of the expected inflation rates remain as topics to be researched in the future.

(2) Limited information on trading volumes has thus far prevented the determination of a benchmark. Based on the results of our econometric analysis, we believe that the Series Three or Four 10 year bonds are strong candidates as a benchmark.

(3) Cost of issuance and performance evaluation have not been adequately discussed. Evaluation is certainly difficult, given the limited number of indexed bonds that have matured to date. Nevertheless, evaluation of financial performance to date can be attempted using realized CPI.

(4) It is known that indexed bonds carry a risk premium or a liquidity premium in comparison to nominal bonds, and these premiums can be specified using calculations. While it is unlikely that these calculations will affect the general direction of the findings of this paper, it is nevertheless worthwhile to perform them.

Appendix. Bloomberg Method for Deriving Real Yield

Market price and yield data for U.S. inflation indexed bonds are made widely available by Bloomberg. In this paper, we have basically relied on Bloomberg for data concerning prices and yields for both the indexed bonds and the nominal bonds. The same information appears daily in the *Wall Street Journal*. Similarly, price and yield data for U.K. government indexed bonds are published in the *Financial Times* and are widely used by financial market participants. That is, market participants use these data in making day-to-day investment decisions and for advising their customers. For instance, under "Real Interest Rates and Expected Inflation rate as Indicated by 10 Year Indexed Government Bonds" (Figure 17) in "Current Investment Strategies" (September 6, 2002, Issue No. 250) of Deutsche Securities (Deutsche Bank Group), Bloomberg data are used to derive the yield differential between normal government bonds and indexed bonds, which is defined as the expected inflation rate.

It appears that the real yield of indexed bonds as made available on Bloomberg monitors is calculated as follows.

(1) The average CPI inflation rate for the year immediately preceding the issuance of the indexed bond is obtained and used as the indexed bond's assumed inflation rate ($\bar{\pi}$).

(2) The assumed nominal coupon (interest) rate ($\bar{C}$) is obtained by adding the indexed bond's contracted real interest rate (r) to the assumed inflation rate ($\bar{\pi}$).

(3) The value of coupon $\bar{C}$ is inserted into "coupon rate C_{nb}" in equation (7) above to obtain nominal yield $\bar{R}$.

(4) Assumed inflation rate $\bar{\pi}$ is subtracted from $\bar{R}$ to arrive at real yield. Real yield $\bar{r} = \bar{R} - \bar{\pi}$

Bloomberg's assumed real yield ($\bar{r}$) differs widely from our real yield (r) derived using equation (6). (See Figure A-1 for calculation of real yield of the Series One 10 year bond.) The variance arises because the Bloomberg equation differs from equation (6) used by the U.S. Treasury. Specifically, price fluctuations, albeit with a three-month lag, are continuously fed into the Treasury Department's equation (6) for valuing indexed bonds.

In Bloomberg's simplified method, the inflation rate prevailing before issuance is used throughout without modification. For instance, the assumed inflation rate for the Series One 10 year bond is 2.903% (1.4515% for half-year), and this figure is used without modification until the bond matures ten years later. While the gap between the assumed and realized rates of inflation is small immediately after issuance, it progressively increases with the passage of time.

The unwitting use of biased data by capital market participants leads to various problems. Discussions of the level and direction of the expected inflation rate without regard to this bias not only generates errors in the investment strategies of market participants but also poses a problem in monetary policy formation. Unfortunately, this problem is not unique to the Bloomberg data. Exactly the same problem exists for real yields on U.K. government-indexed bonds published in the *Financial Times*.

In the case of the Japanese government indexed bonds, it would be highly desirable for market data providers and business newspapers to derive and to publish real yields using the same method employed by the Ministry of Finance in its formal announcements.
